ABSTRACT: Graphene provides a two-dimensional platform for contacting individual molecules, which enables transport spectroscopy of molecular orbital, spin, and vibrational states. Here we report single-electron tunneling through a molecule that has been anchored to two graphene leads. Quantum interference within the graphene leads gives rise to an energy-dependent transmission and fluctuations in the sequential tunnel-rates. The lead states are electrostatically tuned by a global back-gate, resulting in a distinct pattern of varying intensity in the measured conductance maps. This pattern could potentially obscure transport features that are intrinsic to the molecule under investigation. Using ensemble averaged magneto-conductance measurements, lead and molecule states are disentangled, enabling spectroscopic investigation of the single molecule.

KEYWORDS: molecular electronics, graphene, nanoelectrodes, single-electron tunneling

Graphene electrodes are advantageous for use in single-molecule devices,1–5 because unlike metal electrodes, they do not suffer from high atomic mobility and screening.1,3 Large area single-layer graphene can be grown and patterned into devices with electrodes separated by nanogaps,6,7 and molecules bridging the gap can be anchored to the electrodes via covalent bonding8 or π–π-stacking.1–3,8,9 However, the nontrivial density of states and transmission in graphene nanostructures, combined with the fact that graphene can be electrostatically gated, can lead to the observation of transport features in graphene-based single-molecule devices that are not intrinsic to the molecule under investigation, but are rather a property of the leads. Experimental and theoretical studies have shown that quantum interference in graphene ribbons10–13 and nanoconstrictions14 lead to conductance fluctuations at cryogenic temperatures. Quantum confinement in the source and drain electrodes of semiconductor single-electron transistors results in the observation of density of states oscillations in the sequential electron tunneling transport through these devices15,16. It is therefore to be expected that quantum interference effects in graphene electrodes will also influence the charge transport in single-molecule devices.

Here we present a transport spectroscopy investigation of a graphene-based single-electron transistor where we attribute the sequential electron tunneling to the presence of a single molecule bridging the graphene nanogap. While the charge island is most likely formed by an individual zinc-porphyrin dimer, the observed transport features are completely independent of the type of molecule used, and in fact can also be observed in graphene quantum dots in a similar device geometry (see Supporting Information, where we present experimental data of zinc-porphyrin monomers and graphene quantum dots). Our experiments show how the graphene leads couple electrostatically to a global back-gate, and that hybridization between the lead and molecule states results in distinct fluctuation patterns as a function of gate and bias voltage. This behavior is captured by a simple tight-binding model, which we solve both analytically and numerically.

RESULTS AND DISCUSSION

We measured charge transport in single-molecule transistors at 4.2 K (sample A) and 20 mK (sample B) as a function of bias...
voltage $V_s$ and gate voltage $V_g$. Individual molecules were contacted using chemical vapor deposition (CVD) grown graphene nanogaps on a silicon substrate with a 300 nm thermally grown oxide layer that was prepatterned with metal (Cu/Au) contacts. The single-layer nature of the graphene was confirmed by Raman spectroscopy. The graphene nanogaps were fabricated using feedback-controlled electroburning. Single zinc-porphyrin dimer molecules were deposited from a chloroform solution, and were identified by comparing current maps as a function of $V_s$ and $V_g$ before and after deposition (see Supporting Information).

We have measured a total of 171 successfully electroburnt devices (meaning they were successfully burnt, did not break during the wire-bonding and cool-down procedure, and resulted in a measurable tunnel current at 77 K.) From these 171 devices, 109 were measured again at 77 K after the molecular deposition after which 26 devices appeared empty before the deposition (i.e., no Coulomb diamonds) and showed sequential tunneling after molecular deposition. We observed conductance fluctuations in 4 devices.

The conductance through the single zinc-porphyrin dimers was investigated using single-electron tunneling from a metallic source reservoir via the left graphene lead, through the molecule, to the metallic drain reservoir via the right graphene lead (Figure 1a). The silicon substrate was used as a backgate to apply $V_g$. In contrast with metal-based single-molecule transistors, where the metal electrodes screen the gate electric field, in our devices the electrostatic gating influences both the molecular orbital states and the states in the graphene leads (Figure 1b). Previous experiments using partially electroburnt graphene nanoconstrictions have shown that the transmission of our graphene leads fluctuates as a function of $V_s$ and $V_g$, which we attribute to either universal conductance fluctuations (UCFs) resulting from random disorder or the presence of multimode Fabry-Pérot interferences. These fluctuations in the graphene leads influence the transmission through the molecule as orbital states are tuned in and out of resonance with the lead states.

Figure 1c shows the differential conductance measured as a function of the applied bias and gate voltage for sample A. The data reveal a dense set of positive and negative conductance resonances visible as red and blue lines of positive slope that we attribute to fluctuations in the graphene leads. A striking feature of the data is that the red and blue lines do not run parallel to the lines at the edges of white regions of suppressed conductance. In what follows, we will discuss the origin of the conduction resonances and analyze the electrostatic gating of the molecule and the lead states.

For charge to flow through a molecule, electrons need to be added and removed from it. The energy required to add one electron to the molecule, i.e., its electron affinity, is given by the electrochemical potential $\mu_{M} = U(N) - U(N - 1)$, where $U(N)$ is the total energy of the N-electron redox state. This electrochemical potential consists of the discrete orbital energy plus the electrostatic contribution to the energy, which depends linearly on the source (drain) $V_s$ and gate $V_g$ voltage as $\mu_{M} = -\frac{1}{e}C_{A}V_{s} + C_{A}V_{d} + C_{g}V_{g}/(C_{A} + C_{d} + C_{g})$, where the capacitance $C_{d} + C_{g}$ describes the electrostatic interaction between the source (drain, gate) electrode and the molecule. Electrons can tunnel through the molecule when its electrochemical potential is within the bias window defined by the electrochemical potentials $\mu_{s} = -eV_{s}$ and $\mu_{d} = -eV_{d}$ in the
source and drain reservoirs, respectively. When \( \mu_d \) is outside this bias window, electrons do not have the necessary energy to occupy/empty an orbital, resulting in diamond-shape regions of Coulomb blockade in the conductance versus bias and gate voltage map. The slopes of these Coulomb diamonds are given by the conditions \( \mu_s = \mu_d \) and \( \mu_M = \mu_d \). When the device is biased asymmetrically and the gate voltage is set relative to one of the electrodes, in our case the drain, i.e., \( V_s = V_b \) and \( V_d = 0 \), these conditions yield the slopes \( C_{g,M}/(C_{d,M} + C_{g,M}) \) and \( -C_{s,M}/C_{g,M} \).

Similar to the molecular orbital states, the states in the graphene leads shift linearly as a function of the applied bias and gate voltage. The energy shift of the states in the left lead, which is coupled to the source reservoir, is given by \( \Delta \epsilon_{\ell,s} = -\epsilon_{\ell,s} \) (\( C_{s,\ell,L} + C_{s,\ell,M} \)) and for the right lead coupled to the drain reservoir \( \Delta \epsilon_{r,\ell} = -\epsilon_{\ell,s} \) (\( C_{s,\ell,R} + C_{s,\ell,M} \)). In the case of asymmetric biasing, lines in the conductance map for which a molecular orbital aligns with a state in the left lead have a slope given by \( \mu_M = \Delta \epsilon_{\ell,s} \), which yields

\[
\frac{dV_b}{dV_g} = \frac{C_{g,M} + C_{s,M}}{C_{g,M} + C_{d,M}} - \frac{C_{s,M} + C_{s,M}}{C_{g,M} + C_{d,M}} \tag{1}
\]

and for states in the right lead \( \mu_M = \Delta \epsilon_{\ell,r} \) yields

\[
\frac{dV_b}{dV_g} = \frac{C_{g,R}(C_{s,R} + C_{d,R})}{C_{g,R} + C_{d,R}} \tag{2}
\]

When the lead states are clamped to the electrochemical potential of the reservoirs, i.e., if the capacitive coupling between the leads and the gate is zero, the slope of the lines for which the molecular orbitals align with the lead states run parallel to the edges of the Coulomb diamonds. Parallel lines in conductance maps resulting from disorder and confinement in the leads of single-electron transistors have been studied extensively, for example in STM-fabricated devices in silicon. However, when there is capacitive coupling between the leads and the gate, these lines no longer run parallel to the edges of the Coulomb diamonds, and resonances between molecular and lead states shift in and out of the bias window.

From the slopes of the edges of the Coulomb diamonds in Figure 1c we infer that the ratio \( C_{g,M}/C_{d,M} = (33 \pm 1) \times 10^{-3} \) and \( C_{s,M}/C_{d,M} = (20 \pm 1) \times 10^{-3} \). The relatively strong coupling to the source and drain electrodes compared to the gate electrode is due to the fact that the backgate is separated from the device by a 300 nm layer of SiO\(_2\). Next, we estimate the electrostatic coupling of the lead states to the backgate. We only observe conduction resonances with positive slopes, which implies that we predominantly probe the left lead. From the positive slope of the conduction resonances we find \( C_{g,L}/C_{d,L} = (7 \pm 1) \times 10^{-3} \), indicating that the gate coupling to the molecule is approximately 3–5 times stronger than to the lead states. We attribute the difference in gate coupling between the molecule and the lead states to the higher carrier concentration in the graphene leads, which results in a more effective screening of the gate electric field. The average spacing between the conduction resonances is approximately 5 meV, which is consistent with the conductance fluctuations we have previously observed in partially electroburnt graphene nanoconstrictions.

We will now discuss the hybridization between the lead states and the molecular orbitals as they are tuned in and out of resonance. The current through a molecular orbital is given by the Landauer formula

\[
I = -\frac{2e}{h} \int \left[ T(E) [f_s(E) - f_R(E)] \right] dE \tag{3}
\]

where \( f_{s,R} \) denotes the Fermi distribution of the reservoirs, which in the case of asymmetric biasing depends on the bias voltage \( V_b \) and temperature \( T \) as \( f_s = \frac{\exp((E - eV_b)/k_B T)}{[\exp((E - eV_b)/k_B T) + 1]^{-1}} \) and \( f_R = \exp(E/k_B T)/[\exp(E/k_B T) + 1]^{-1} \).

To investigate the role of scattering in the leads on the transmission through the molecular orbital we employ a simple Hückel (tight-binding) model as shown in Figure 2a. The molecule is represented by a single site at \( n = 0 \) with an on-site energy \( \mu_M \) and a hopping integral \( t_{l,R} \) to the left and right lead, respectively. The left and right leads are represented by semi-infinite chains with on-site energies \( \epsilon_{l,R} \) and nearest-neighbor hopping integrals \( \alpha_{l,R} \). We introduce scattering into the left and right compound electrodes at \( n = -N_L \) and \( n = N_R \) by adjusting the hopping integrals \( \alpha_{l,R} \).

Traditionally one would regard this structure as a complicated scatterer (S) consisting of the region between \( -N_L \leq n \leq N_R \) (shaded gray in Figure 2b) and two simple crystalline leads (shaded orange in Figure 2b) along which electrons propagate ballistically into and from the reservoirs. For such a system,

\[
T(E) = 4\text{Tr} \left[ \Gamma_A G_{SS}^L \Gamma_B G_{SS}^R \right] \tag{4}
\]

where \( \Gamma_A \) and \( \Gamma_B \) describe the level broadening due to contact with the crystalline semi-infinite leads, A and B. In this expression, the scattering region is a complex combination of the molecule and graphene and \( G_{SS} \) is the Green’s function of the scattering region in the presence of the simple crystalline leads. Our aim is to separate the contributions to scattering from the molecule and graphene and therefore we adopt an alternative formulation in which the left graphene, and left semi-infinite lead, i.e., the region \( n < 0 \), are regarded as a compound electrode (L) and the right graphene and right semi-infinite lead (\( n > 0 \)) form the right compound electrode (R). This viewpoint is encapsulated in the following alternative expression for the transmission coefficient, which is mathematically equivalent to eq 4.

Figure 2. Partitioning the molecule-lead system. (a) Schematic depiction of the Hückel model. (b) Partitioning of the system into simple electrodes A and B with a complex scattering region S, and (c) into “compound electrodes” L and R and a simple scattering site M.
$T(E) = 4T\Gamma [g_{\text{LM}}G_{\text{MM}}G_{\text{RM}}^\dagger]$ (5)

In this equation, the level broadening due to contact between the molecule and the left and right compound electrodes are described by

$\Gamma_L = H_{\text{ML}}g_{\text{LL}} - g_{\text{LL}}^\dagger H_{\text{LM}}^{-1}$ (6)

$\Gamma_R = H_{\text{MR}}g_{\text{RR}} - g_{\text{RR}}^\dagger H_{\text{RM}}^{-1}$ (7)

where $g_{\text{LL(RR)}}$ is the Green’s function of the isolated left(right)-hand compound electrode, and $H_{\text{LR}}$ denotes the coupling between the left(right) compound electrode and the molecule. The Green’s function of the molecule in the presence of the compound electrodes is given by

$G_{\text{MM}} = (E - \mu_M - \Sigma_L - \Sigma_R)^{-1}$ (8)

where the self-energies of the left and right compound electrode are

$\Sigma_L = H_{\text{ML}}g_{\text{LL}}H_{\text{LM}} = \sigma_L - i\Gamma_L$ (9)

$\Sigma_R = H_{\text{MR}}g_{\text{RR}}H_{\text{RM}} = \sigma_R - i\Gamma_R$ (10)

Using eqs 5 and 6–10, we obtain the Breit–Wigner formula

$T(E) = \frac{4T\Gamma_R}{(E - \mu_M - \sigma_L - \sigma_R)^2 + (\Gamma_L + \Gamma_R)^2}$ (11)

In the case of the simple Hückel model, this implies that the tunnel-rate $\Gamma_\alpha$ is proportional to the local density of states at site $n = -1$ and $\Gamma_\alpha$ is proportional to the local density of states at site $n = +1$. Both the tunnel-rates and the energy shifts depend on the electrode density of states, which in turn is determined by the random locations of scattering centers within the graphene electrodes. The self-energies of the compound electrodes in the Hückel model can be found numerically by decimation (for details see Supporting Information), or analytically by solving Dyson’s equation (see Supporting Information). The latter yields

$\Sigma_L = -\frac{2}{\alpha_L} e^{-i\alpha_L^2} e^{-\beta_L/\alpha_L^2} \sin k_L - x_L \sin k_L (N_L - 1)$

$\alpha_L e^{-i\alpha_L^2} \sin k_L - x_L \sin k_L N_L e^{i\beta_L}$ (12)

where $x_L = \beta_L/\alpha_L^2 - 1$ and $k_L = \cos^{-1}(\epsilon_L - E)/2\alpha$. Similarly $\Gamma_R$ is obtained by replacing $L$ by $R$ in the above expression. Here we have derived the transmission for a simple one-dimensional Hückel model, however eqs 4 and 5 are completely general, and the transmission function will depend on the details of the system Hamiltonian (see Supporting Information for a more sophisticated system Hamiltonian). Experimentally, we find that the position of the molecular energy level with respect to the Fermi energy of the leads and the strength of the coupling between the molecule and the graphene leads varies significantly from device to device.

Figure 3a,b shows the real and imaginary part of the self-energies for strong and weak reflections in the leads. For strong reflection ($\beta_L^2 = 0.1\alpha_L^2$), we find sharp peaks in the imaginary part of the self-energies, i.e., the density of states at the surface sites ($n = \pm 1$), arising from quasi-bound states between the molecule and the reflection sites ($n = -N_L, N_R$). By contrast, for weak reflections ($\beta_L^2 = 0.9\alpha_L^2$) we find a small sinusoidal modulation of both the tunnel-rates $\Gamma_{LR}$ and the energy shift $\sigma_{LR}$. The tunnel-rate is maximum on resonance with the quasi-bound lead states while the hybridization energy changes sign upon crossing the resonance condition. The transmission as a function of energy $E$ and on-site potential $\mu_M$ for $\gamma_{LR} = 20$ meV.
= 20 meV results in a good qualitative agreement between the experimental and theoretical differential conductance maps. Due to strong asymmetry in coupling strength between the left and right lead, i.e., $\Gamma_L \ll \Gamma_R$, the amplitude of the Breit–Wigner resonance $\sim \Gamma_1$ and is only sensitive to states in the left lead.

The conductance fluctuations observed in the sequential tunnelling regime arise from interference effects in the leads, which can either be the result of scattering of random impurities leading to universal conductance fluctuations (UCFs, see Figure 4a), or Fabry–Pérot (FP, see Figure 4b) interferences resulting from reflections at potential barriers. UCFs can be observed if electron waves scatter along closed trajectories and the phase coherence length $l_P$ is larger than the mean free path. This scattering leads to random, energy dependent interferences within segments of $l_P$ inside the conductor which appear as aperiodic conductance fluctuations as a function of gate voltage. When a magnetic field is applied perpendicular to the graphene leads, electron waves acquire an additional phase due to the vector potential, resulting in an Aharonov–Bohm phase $\Delta B_{AB} = \Phi_0/S$, where $\Phi_0 = h/e$, for a trajectory enclosing an area $S$. When the conductance is measured for different magnetic fields within the correlation field scale $\Delta B_c = \Phi_0/(L_x + L_y)$, where $L_x$ and $L_y$ correspond to the smallest relevant dimension in $x$ and $y$ direction, similar features corresponding to a specific impurity configuration are observed in each conductance curve.21,22 However, when the increments in external magnetic field are larger than $\Delta B_c$, a different impurity configuration is probed for each conductance curve. As a result, UCFs can be suppressed by ensemble averaging measurements recorded at $B > \Delta B_c$, denoted by $\langle \cdots \rangle_B$. This technique was successfully used to distinguish between UCF and weak-localization effects in nanowires23 and carbon nanotubes.24 Theoretically, the UCFs can be reduced by a factor of $\sqrt{N}$ where $N$ is the size of the ensemble.25 Figure 4f shows bias traces as a function of magnetic field recorded at $V_g = 29.75$ V of sample B measured at 20 mK (indicated by the dotted line in Figure 4c). We recorded 40 traces in $B_{\parallel} = B_z$ (Figure 4d) and 40 traces in $B_L = B_x$ (Figure 4e). For a phase coherence length $l_P \approx 400$ nm14 found in our graphene samples, $\Delta B_c \approx 25$ mT, and therefore $\Delta B_{AB} > \Delta B_c$. While the out-of-plane magnetic field changes the conductance fluctuations (Figure 4e), the in-plane field up to 6 T does not affect the oscillations (see Figure 4d). The fact that only the out-of-plane magnetic field influences the conductance fluctuations further strengthens our assumption that they are intrinsic to two-dimensional graphene leads rather than the molecule. By comparing the conductance at $B = 0$ with the data averaged over $B$ we find a reduction of UCFs of $\text{var}(G(B = 0))/\text{var}((G(B))^B) \approx 6$ very close to the theoretical value of $\sqrt{40} \approx 6.3$.

Single- and multimode FP interference effects have previously been observed in graphene ribbons and nanostripes.16 The Lorentz force acting on the electrons in a FP cavity will curve their trajectories when an external magnetic field is applied, which leads to the semiclassical (kinetic) phase difference $\phi_{\text{WKB}}$ between two neighboring trajectories.25 In addition, bent trajectories enclosing an area $S$ will accumulate an Aharonov–Bohm phase $\phi_j = eB_zS/h = \Phi_0/\Phi_0$. Finally, back-reflected electrons in graphene acquire a Berry phase $\phi_{\text{Berry}}$ which is $\pi$ for single-layer graphene and can take values between 0 and $2\pi$ in bilayer graphene depending on its carrier density and asymmetry parameter, which is defined as the difference in on-site energies of the two graphene layers.26 Since the Berry phase is not affected by the external magnetic field, and therefore does not play a role in magnetic-field averaging, it can be ignored in this discussion. The resonance condition for Fabry–Pérot interferences is met when $\phi_{\text{WKB}} + \phi_{\text{AB}} + \phi_{\text{Berry}} = 2\pi j$ where $j \in \mathbb{Z}$. Variations of the external magnetic field will change this condition and thus shift the conductance maxima due to the combined influence on $\phi_{\text{WKB}}$ and $\phi_{\text{AB}}$ (see Supporting Information). Ensemble averaging of the magneto-conductance traces will therefore result in the suppression of density of states fluctuations. This behavior can be illustrated by a tight-binding model shown in Figure 5a, in which the leads contain circular regions through which a magnetic flux can pass. Again the transmission coefficient can be obtained analytically as a function of the flux $\Phi$ passing through each of the loops. This is imposed via a Peierls substitution by adding a phase factor $\theta = 2\pi \Phi/\Phi_0$ to nearest

![Figure 4](image-url)
To conclude, our results highlight the importance of the electronic properties of the lead electrodes in single-molecule electronics. While graphene may be a material system that is very well suited to host these devices, further understanding of the hybridization between graphene and molecules will be needed to develop these devices into a technology. Atomically precise control of the structure and edge termination of the graphene leads, together with stacked two-dimensional material approaches could enable functional graphene-molecule hybrid systems.

METHODS

Devices are fabricated using feedback-controlled electroburning of CVD grown graphene ribbons that were wet-transferred onto a pre-patterned Si/SiO₂ chip containing Au/Cr contact pads. We deposit molecules from a 10 μM chloroform solution. Devices were measured in an Oxford Instruments Triton 200 dilution refrigerator and a custom-built liquid helium dipper. Measurements were performed using low-noise, battery powered electronics. We measure the transport characteristics of the device before and after molecular deposition and select those device that only show Coulomb blockade after deposition.
